

An initial attempt at a spatially structured stock assessment for the South African hake resource including explicit movement

Rebecca A. Rademeyer

November 2013

SUMMARY

The distribution area for the South African hake population is separated into nine regions to accommodate an initial attempt at a model of the dynamics which reflects explicit movement of the two species of hake both longshore and offshore. Commercial selectivities-at-length are modelled by logistic curves to reflect a gear only and no availability effect, but it proves necessary to allow for doming in the survey selectivities-at-length. Although most abundance and size structure data are reasonably well fitted by the model, the model tends to overestimate the proportion of hake in the smallest and largest length groups for the surveys. Spawning biomass trends for *M. paradoxus* and *M. capensis* are broadly similar to those estimated by the current assessment approach which uses differing selectivity patterns by species and area as a surrogate for movement. Suggestions are made regarding issues for possible further investigation.

INTRODUCTION

This paper documents the attempt at developing a spatially structured model for the South African hake which includes movement explicitly. The current assessments assume that *M. paradoxus* and *M. capensis* each comprise a single stock across the South African west and south coasts. From catch-at-length information, it is however clear that the fish are not distributed evenly in terms of age/length in different areas. The current assessment of the resource treats the each hake species as homogeneously distributed throughout the whole region, and reflects the different age/length structure on the west and south coasts by assuming different fishing selectivities-at-age for the commercial and survey fleets (so selectivity here combines both gear and availability effects). In the spatial model being developed which is reported herein, however, the survey and commercial fishing selectivities-at-age are taken to be the same across all regions. The regional differences in the age/length distributions of the catches are therefore explained instead by the different proportions of each age class in each region. This approach would provide a convenient framework for extension to include hake off Namibia in due course.

The model currently includes nine regions which follow the present survey area stratifications, so that all the survey data are readily available in this form:

- | | |
|--------------------------|-------------------------------|
| 1. west coast, 0-100m; | 6. south coast, 0-50m; |
| 2. west coast, 101-200m; | 7. south coast, 51-100m; |
| 3. west coast, 201-300m; | 8. south coast, 101-200m; and |
| 4. west coast, 301-400m; | 9. south coast, 200m+. |
| 5. west coast, 401m+; | |

The offshore trawl catches from 1978 onwards can also be disaggregated by region using the catch and effort data base. For the inshore trawl, longline and handline fleet some coarse assumptions are being made - see

Appendix A, Table A.1. Since splitting the pre-1978 commercial data by regions and species would involve too many assumptions, it was decided rather to start disaggregation in terms of the assumed spatial structure in 1978. From 1917 to 1977 therefore, the model is a coast combined assessment; it uses the same assumptions to split the offshore trawl catches by species and fit the ICSEAF CPUE as in the current assessment (Rademeyer and Butterworth, 2013). In the beginning of 1978, the fish are distributed by age groups amongst the different regions.

The hake are modelled to move across regions through the use of movement matrices, which reflect the probability that a fish of a particular age in region r' at the start of the year, moves to region r at the end of the year. These matrices are estimated for three age groups (rather than estimate a different matrix for each age class): a) ages 0-1, b) ages 2-4 and c) ages 5 and above, and are assumed to be constant over time (but variability in the form of random effects could also be included in the future if the data support their estimation). During the December 2011 Assessment Workshop, a small group met to try reducing the number of movement parameters to be estimated by flagging regions in which species and age group combinations could be assumed not to be present. The resulting matrices of estimable parameters are shown in Fig. 1.

DATA AND METHODS

The data are described in Appendix A and the methods in Appendix B.

Some notes concerning key elements of the methodology applied

- Given that movement is modelled explicitly, any “selectivity” effect remaining should reflect gear selection only. Accordingly all commercial selectivities-at-length have been modelled by logistic functions (see Appendix B section B3.1.3). However fits to the data would not then accept a similar form for the survey selectivities-at-length, which were accordingly modelled using a more flexible form (see Appendix B section B3.1.2 for details).
- The Beverton-Holt stock-recruit relationship was used.
- Natural mortality was fixed for both species, with $M_{2-}=0.75$ and $M_{5+}=0.375$, and a linear trend between these ages.

RESULTS

Table 2 gives some results for *M. paradoxus* and *M. capensis*. The different contributions to the negative log-likelihood are given in Table 3. Table 4 shows the estimated multiplicative factors for each survey and species.

The total catches by species and the catches disaggregated by region and species assumed are shown in Figs 1 and 2 respectively.

The total spawning biomass trajectories estimated for each species are plotted in Fig. 3. In Fig. 4, the spawning biomasses are disaggregated by region.

The survey commercial selectivities-at-length estimated when fitting the model are shown in Fig. 5.

The estimated stock-recruitment curve and the trajectories of recruitment are plotted in Fig. 6 for each species.

The fits to the CPUE series are plotted in Fig. 7, while Fig. 8 plots the fits to the region-disaggregated survey biomass indices.

The fits to the commercial age- and length-distributions are shown in Fig. 9. The fits to the region-disaggregated survey length-distributions are shown in Fig. 10.

The estimated movement matrices are given in Table 5, while the resulting proportions of each age in each region are given in Table 6.

DISCUSSION

Initially, problems were encountered in estimating the movement parameters. An attempt was made to reduce the number of regions to five. However, this did not prove satisfactory as a single selectivity could not adequately reflect the age/length distributions in those five regions.

Many of the logistic commercial selectivity curves estimated (Fig. 6) reflect near knife-edge selection. However the curves for the surveys are strongly domed shaped. The reasons for this dome are unclear at this stage. It may be related to the surveys not covering areas deeper than 500 m where the largest hake predominate, but could also reflect some mis-specification of the model.

The fits to the CPUE data series (Fig. 7) and survey indices (Fig. 8) are broadly reasonable, though the model shows the occasional surprising spike for the former, which warrants further investigation.

The fits to the year-aggregated commercial catch-at-age and catch-at-length data (Fig. 9) are also broadly reasonable. However for the survey catch-at-length data (Fig. 10) there are areas in need of improvement, particularly as regards the model often suggesting much higher proportions in the minus- and/or plus-group than are observed.

Estimates a q values well above 1 for the south coast surveys (Table 5), implying substantial herding of hake by the survey nets, seem surprising and merit further investigation.

Overall the estimated spawning biomass trajectories are broadly similar to those estimated by the assessment method used at present (Rademeyer and Butterworth 2013) – see Table 2 and Fig. 3 – with the status of *M. paradoxus* being estimated to be slightly better, and that of *M. capensis* slightly worse, than for the current Reference Case (RS1) assessment.

AREAS FOR POSSIBLE FUTURE WORK

- The potential and fundamental advantage of a model estimating movement explicitly is that gear-selectivity “should” be asymptotically flat, i.e. the confounding of emigration (causing selectivity doming) and fishing mortality in conventional models falls away. Some of the fits to size structure data suggest moving to more flexible selectivity models than the logistic, but this would re-introduce this confounding problem.
- Another option would be to accept that difficulty, and move back to a model without movement, keep the nine regions and model the different age/length structure by estimating different selectivities in the different regions, i.e. the Rademeyer and Butterworth (2013) approach, but with a more complex spatial structure to fit size-structure data better.
- Starting the movement in 1978 only as in the present model is not ideal and may not be the best solution.
 - The progressive move of the offshore trawl fishery to deeper waters over the 1917-1977 period could be modeled internally; this would also provide a better way to model the ICSEAF CPUE series than the current method (Appendix B, section B.2.1).

- The pre-1978 selectivities are taken to be the same as post-1977, but the model is not region-disaggregated for this earlier period. The pattern of removals by length is thus not correctly represented over this period, leading to a bias in the 1978 age structure to which the movement model is then applied to project the two species through the following years.
- There is also the problem of how to distribute the fish in 1978. At the moment, the proportions in each region are computed from the movement matrices. The different proportions could rather be made estimable parameters with some functional relationships to reduce the number of parameters. Another solution might be to start moving the fish spatially before 1978 (let's say 20 years before), to have settled population by 1978 - i.e. although the model is aggregated over regions (i.e. the catch is taken from the whole population), the model could keep track of the proportion of fish moving and multiplying the resulting proportions by the numbers-at-age.
- Leslie and Somhlaba (2013) provide revised assumptions to disaggregate the data from the longline fleet by species and regions. This information was not used here as it was not provided in the right format, but it should be considered for use in the future.
- Since there is depth information for the offshore trawl catches from 1978, region-specific GLM-standardised CPUE series could be developed and fitted to in this model, rather than use coast-specific indices.

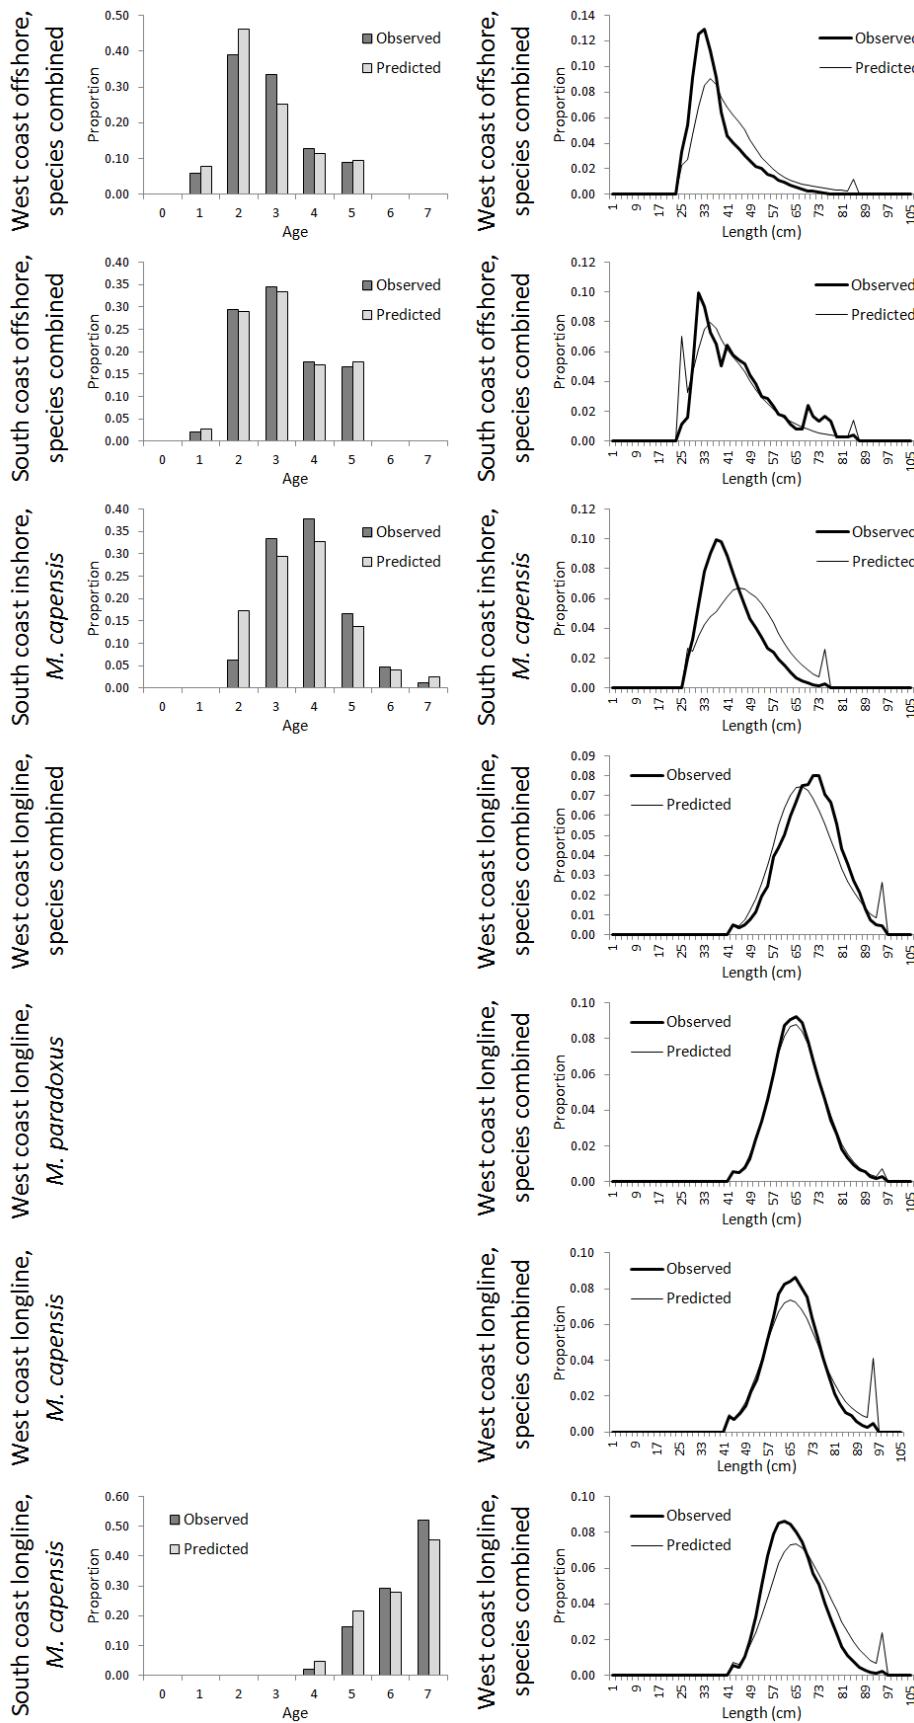

Fig. 9: Fits to the commercial catch-at-age and commercial catch-at-length data, averaged over all the years for which data are available.

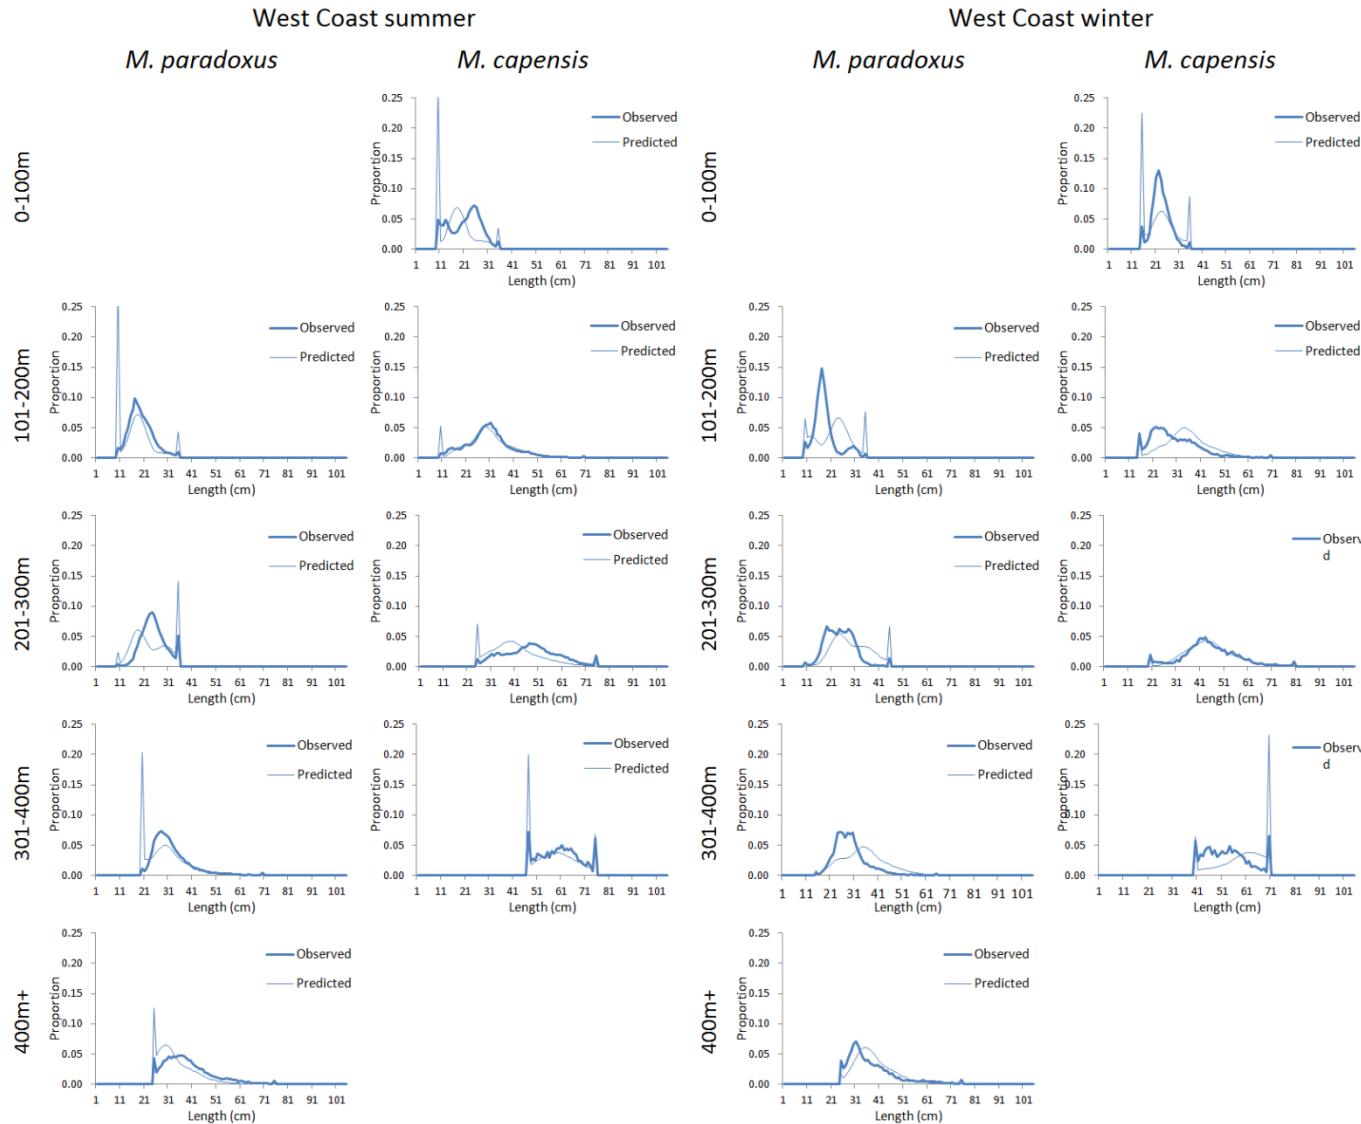

Fig. 10a: Fits to the west coast summer and west coast winter survey region specific catch-at-length data, as averaged over all the years for which data are available.

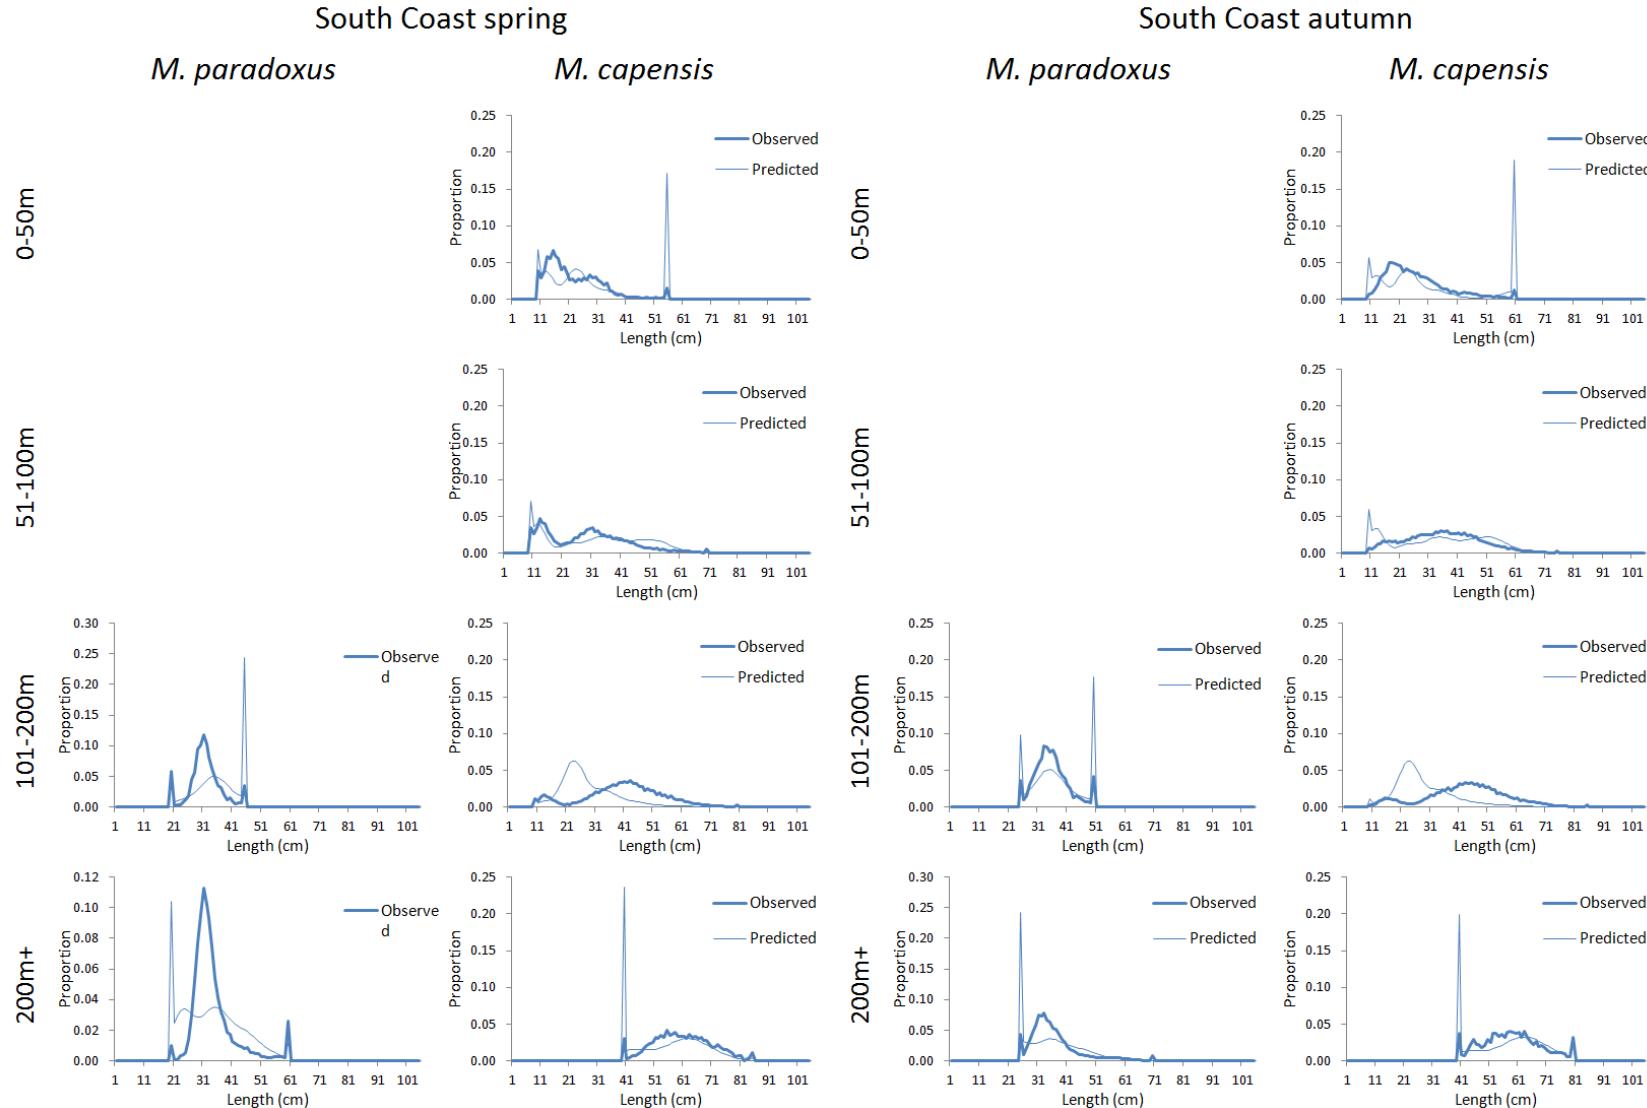

Fig. 10b: Fits to the south coast spring and south coast survey region specific catch-at-length data, as averaged over all the years for which data are available.

Appendix A: Data used

A.1 Catches

A.1.1 Offshore trawl

The offshore trawl catches from 1978 can be disaggregated by region using the catch and effort data base. These are given in Table A1. The offshore trawl fleet is assumed to operate in waters deeper than 200m on the West Coast and deeper than 100m on the South Coast. The catches actually recorded in shallower depths (average of 2% on the West Coast and 1% on the South Coast) were attributed to the "201-300m" region on the West Coast and to the "101-200m" region on the South Coast.

Since splitting the pre-1978 commercial data by regions and species would involve too many assumptions, it was decided rather to start disaggregation in terms of the assumed spatial structure in 1978. From 1917 to 1977 therefore, the model is a coast combined assessment; it uses the same assumptions to split the offshore trawl catches by species and fit the ICSEAF CPUE as in the current assessment (Rademeyer and Butterworth, 2013). The pre-1978 offshore trawl catches are given in Table A2.

A.1.2 Other fleets

To split the inshore trawl, longline and handline catch by region, some coarse assumptions need to be made - see Table A.3. To split the catches by species, the same assumptions are made as in the Reference Case, i.e. 100% *M. capensis* for the inshore, longline and handline catches on the South Coast and 30% *M. capensis* for the West Coast longline catches. The catches for each of these fleets are given in Table A.4.

A.1.3 CPUE

Six CPUE time-series are used: a historic CPUE series for each of the South and West coasts and a GLM-standardised CPUE series for each species and coast - see Table A.5.

A.1.4 Survey biomass indices

Survey biomass indices are available by species and by region for four surveys: West Coast summer, West Coast winter, South Coast spring and South Coast autumn - see Table A.6.

A.1.5 Commercial catches-at-age and -at-length

The commercial age and length distributions available are given in Table A.7. These data are not disaggregated by region.

A.1.6 Survey catches-at-length

Survey length distributions are available by species and disaggregated by region. The data available are shown in Table A.8.

Table A1: Offshore trawl catches disaggregated by region from 1978 onwards.

Appendix B: Methods

B.1 Population Dynamics

r : an index for region, $r=1, \dots, n_{region}$ (here $n_{region}=9$)

y : an index for year

a : an index for age, $a=0, \dots, m$ ($m=15$, a plus group)

l : an index for length $l=1, \dots, l_{max}$ ($l_{max}=105$)

f : an index for fleet, $f=1, \dots, n_{fleet}$ ($n_{fleet}=4$)

The equations below apply to each hake species, with different parameter values by species. The species indices have been omitted to avoid clutter.

Since too many assumptions would have to be made to disaggregate the catches by region and species pre-1978, the decision was made to model a single region pre-1978 and to include movement only from 1978 onwards.

B1.1 Numbers-at-age:

Pre-1978, the model is not region dependent:

$$N_{y+1,0} = R_{y+1} \quad (B1)$$

$$N_{y+1,a+1} = \left(N_{y,a} e^{-M_a/2} - \sum_f^{n_{fleet}} C_{y,a}^f \right) e^{-M_a/2} \quad \text{for } 0 \leq a \leq m-2 \quad (B2)$$

$$N_{y+1,m} = \left(N_{y,m-1} e^{-M_{m-1}/2} - \sum_f^{n_{fleet}} C_{y,m-1}^f \right) e^{-M_{m-1}/2} + \left(N_{y,m} e^{-M_m/2} - \sum_f^{n_{fleet}} C_{y,m}^f \right) e^{-M_m/2} \quad (B3)$$

From 1978 onwards, region-disaggregation and movement between regions are included:

$$N_{y+1,0}^r = \left(\frac{1}{n_{region}} \sum_{r'}^{n_{region}} X_{y+1,0}^{\text{outr}',\text{in } r} \right) R_{y+1} \quad \text{for } a=0 \quad (B4)$$

$$N_{y+1,a+1}^r = \sum_{r'}^{n_{region}} \left(\left[\left\{ N_{y,a}^{r'} e^{-M_a/2} - \sum_f^{n_{fleet}} C_{f,y,a}^{r'} \right\} e^{-M_a/2} \right] X_{y,a}^{\text{outr}',\text{in } r} \right) \quad \text{for } 0 \leq a \leq m-2 \quad (B5)$$

$$N_{y+1,m}^r = \sum_{r'}^{n_{region}} \left(\left[\left\{ N_{y,m-1}^{r'} e^{-M_{m-1}/2} - \sum_f^{n_{fleet}} C_{f,y,m-1}^{r'} \right\} e^{-M_{m-1}/2} \right] X_{y,m-1}^{\text{outr}',\text{in } r} \right) \quad (B6)$$

$$+ \sum_{r'}^{n_{region}} \left(\left[\left\{ N_{y,m}^{r',\text{spp},s} e^{-M_m/2} - \sum_f^{n_{fleet}} C_{f,y,m}^{r'} \right\} e^{-M_m/2} \right] X_{y,m}^{\text{outr}',\text{in } r} \right)$$

i.e. in order through the year: 1) recruit, 2) die of natural causes in first half of the year, 3) catch taken as pulse in the middle of the year, 4) second half year of natural mortality, 5) move.

$N_{y,a}^r$: the number of fish of age a at the start of year y in region r ,

M_a : the natural mortality on fish of age a (assumed to be region independent)

$$M_a = \begin{cases} M_2 & \text{for } a \leq 1 \\ \alpha^M + \frac{\beta^M}{a+1} & \text{for } 2 \leq a \leq 5 \\ M_5 & \text{for } a > 5 \end{cases} \quad (\text{B7})$$

$C_{f,y,a}^r$: the number of fish of species spp , and age a caught in year y and region r by fleet f ,

$X_{y,a}^{r,r'}$: the probability that a fish of age a in region r' at the start of year y moves to region r at the end of that year ($X_{y,a}^{r,r}$ is the probability that the fish stays in region r).

For the moment, $X_{y,a}^{r,r'} = X_a^{r,r'}$, i.e the movement is the same across the years, but variability in the form of random effects could be included later. Furthermore, at this stage, movement is estimated for three age groups: a) ages 0-1, b) ages 2-4 and c) ages 5 and above. Some form of relationship (with random effects), such as forcing older fish offshore, could be included. The movement is not density dependent at this stage.

Distribution of the fish by region in 1978:

$$N_{1978a}^r = \left(\frac{1}{n_{region}} \sum_{r'}^{n_{region}} X_{y+1,0}^{outr',in\,r} \right) N_{1978a}^{tot} \quad (\text{B8})$$

B1.2 Recruitment:

$$R_y = f(SSB_y) \quad (\text{B9})$$

the recruitment (number of 0-year-old fish) at the start of year y , which is a function of the total spawning biomass (SSB_y):

$$R_y = \frac{4hR_0 SSB_y}{K^{sp}(1-h) + (5h-1)SSB_y} e^{(\zeta_y - \sigma_R^2/2)} \quad (\text{B10})$$

for the Beverton-Holt stock-recruitment relationship and

$$R_y = \alpha SSB_y \exp(-\beta (SSB_y)^\gamma) e^{(\zeta_y - \sigma_R^2/2)} \quad (\text{B11})$$

with

$$\alpha = R_0 \exp(\beta (SSB_y)^\gamma) \quad \text{and} \quad \beta = \frac{\ln(5h)}{(SSB_y)^\gamma (1 - 5^{-\gamma})} \quad (\text{B12})$$

for the modified Ricker relationship (for the true Ricker, $\gamma=1$)

$$R_0 = SSB_y / \left[\sum_{a=1}^{m-1} mat_a w_a e^{-\sum_{a'=0}^{a-1} M_{a'}} + mat_m w_m \frac{e^{-\sum_{a'=0}^{m-1} M_{a'}}}{1 - e^{-M_m}} \right] \quad (\text{B13})$$

ζ_y reflects fluctuation about the expected recruitment in year y ;

σ_R is the standard deviation of the log-residuals, which is input ($\sigma_R = 0.45$ and is taken to decrease from this value to 0.1 over the last five years to statistically stabilise estimates of recent recruitment).

B1.3 Spawning biomass:

$$SSB_y = \sum_{r=1}^{n_{region}} \sum_{a=1}^m mat_a w_a N_{y,a}^r \quad (B14)$$

w_a : the begin-year mass of fish of age a

mat_a : the proportion of fish of age a that are mature, converted from maturity-at-length as follows:

$$mat_a = \sum_l mat_l P_{a,l} \quad (B15)$$

$P_{a,l}$ is the begin-year proportion of fish of age a and that fall in the length group l (i.e., $\sum_l P_{a,l} = 1$ for all ages a).

The matrix P is calculated under the assumption that length-at-age is normally distributed about a mean given by the von Bertalanffy equation, i.e.:

$$l_a \sim N[l_\infty(1 - e^{-\kappa(a-t_0)}); \theta_a^2] \quad (B16)$$

where θ_a is the standard deviation of length-at-age a , which is modelled to be proportional to the expected length-at-age a , i.e.:

$$\theta_a = \beta L_\infty (1 - e^{-\kappa(a-t_0)}) \quad (B17)$$

with β an estimable parameter.

B1.4 Catch:

The fleet-disaggregated catch by mass in year y and region r is given by:

$$C_{f,y}^r = \sum_a \tilde{w}_{a+1/2} C_{f,y,a}^r \quad (B18)$$

$$C_{f,y,a}^r = N_{y,a}^r e^{-M_a/2} S_{f,y,a} F_{f,y}^r \quad (B19)$$

$F_{f,y}^r$: the fished proportion of a fully selected age class for fleet f in year y and region r and

$$S_{f,y,a} = \sum_l S_{f,y,l} P_{a+1/2,l} \quad (B20)$$

$S_{f,y,a}$ is the commercial selectivity (not region specific) at age a for fleet f and year y ;

$$\tilde{w}_{f,y,a+1/2} = \sum_l S_{f,y,l} w_l P_{a+1/2,l} / \sum_l S_{f,y,l} P_{a+1/2,l} \quad (B21)$$

$\tilde{w}_{f,y,a+1/2}$ is the selectivity-weighted mid-year weight-at-age a for fleet f and year y ;

w_l is the weight of fish of length l ;

B.2 The likelihood function

The model is fit to CPUE and survey biomass indices, commercial and survey length frequencies, , as well as to the stock-recruitment curve to estimate model parameters. Contributions by each of these to the negative of the log-likelihood ($-\lambda n L$) are as follows¹.

B.2.1 CPUE relative biomass data

The likelihood is calculated by assuming that the observed biomass index (here CPUE) is log-normally distributed about its expected value:

$$I_y^i = \hat{I}_y^i e^{\varepsilon_y^i} \quad \text{or} \quad \varepsilon_y^i = \ln(I_y^i) - \ln(\hat{I}_y^i) \quad (\text{B22})$$

where

I_y^i is the biomass index for year y and series i (which corresponds to a specified species, fleet and sum of regions);

$\hat{I}_y^i = \hat{q}^i \hat{B}_{fy}^{ex}$ is the corresponding model estimate, where \hat{B}_{fy}^{ex} is the model estimate of exploitable resource biomass, given by:

$$\hat{B}_y^{ex} = \sum_r \sum_{a=0}^m \tilde{w}_{y,a}^{mid} S_{y,a} N_{y,a}^r e^{-M_a/2} (1 - S_{y,a} F_y^r / 2) \quad (\text{B23})$$

\hat{q}^i is the constant of proportionality for biomass series i ; and

ε_y^i from $N(0, (\sigma_y^i)^2)$.

The GLM-CPUE series are coast- and species-specific but not disaggregated by region. The West Coast series are taken to apply to the regions "201-300m", "301-400m" and "400m+" combined. The South Coast series are taken to apply to the regions "101-200m" and "200m+" combined.

In cases where the CPUE series are based upon species-aggregated catches (as available pre-1978), the corresponding model estimate is derived by assuming two types of fishing zones: z1) an "*M. capensis* only zone", corresponding to shallow-water and z2) a "mixed zone" (Figure B.1).

The total catch of hake of both species (BS) by fleet f in year y ($C_{BS,fy}$) can be written as:

$$C_{BS,fy} = C_{C,fy}^{z1} + C_{C,fy}^{z2} + C_{P,fy} \quad (\text{B24})$$

where

$C_{C,fy}^{z1}$ is the *M. capensis* catch by fleet f in year y in the *M. capensis* only zone (z1);

$C_{C,fy}^{z2}$ is the *M. capensis* catch by fleet f in year y in the mixed zone (z2); and

$C_{P,fy}$ is the *M. paradoxus* catch by fleet f in year y in the mixed zone.

Catch rate is assumed to be proportional to exploitable biomass. Furthermore, let γ be the proportion of the *M. capensis* exploitable biomass in the mixed zone ($\gamma = B_{C,fy}^{ex,z2} / B_{C,fy}^{ex}$) (assumed to be constant throughout the

¹ Strictly it is a penalised log-likelihood which is maximised in the fitting process, as some contributions that would correspond to priors in a Bayesian estimation process are added.

period for simplicity) and ψ_{fy} be the proportion of the effort of fleet f in the mixed zone in year y ($\psi_{fy} = E_{fy}^{z2}/E_{fy}$), so that:

$$C_{C,fy}^{z1} = q_C^{i,z1} B_{C,fy}^{ex,z1} E_{fy}^{z1} = q_C^{i,z1} (1-\gamma) B_{C,fy}^{ex} (1-\psi_{fy}) E_{fy} \quad (B25)$$

$$C_{C,fy}^{z2} = q_C^{i,z2} B_{C,fy}^{ex,z2} E_{fy}^{z2} = q_C^{i,z2} \gamma B_{C,fy}^{ex} \psi_{fy} E_{fy} \text{ and} \quad (B26)$$

$$C_{P,fy} = q_P^i B_{P,fy}^{ex} E_{fy}^{z2} = q_P^i B_{P,fy}^{ex} \psi_{fy} E_{fy} \quad (B27)$$

where

$E_{fy} = E_{fy}^{z1} + E_{fy}^{z2}$ is the total effort of fleet f , corresponding to combined-species CPUE series i which consists of the effort in the *M. capensis* only zone (E_{fy}^{z1}) and the effort in the mixed zone (E_{fy}^{z2});

$q_C^{i,zj}$ is the catchability for *M. capensis* (C) for biomass series i , and zone zj ; and

q_P^i is the catchability for *M. paradoxus* (P) for biomass series i .

It follows that:

$$C_{C,fy} = B_{C,fy}^{ex} E_{fy} [q_C^{i,z1} (1-\gamma) (1-\psi_{fy}) + q_C^{i,z2} \gamma \psi_{fy}] \quad (B28)$$

$$C_{P,fy} = B_{P,fy}^{ex} E_{fy} q_P^i \psi_{fy} \quad (B29)$$

From solving equations B28 and B29:

$$s_{fy} = \frac{q_C^{i,z1} (1-\gamma)}{\left\{ \frac{C_{C,fy} B_{P,fy}^{ex} q_P^i}{B_{C,fy}^{ex} C_{P,fy}} - q_C^{i,z2} \gamma + q_C^{i,z1} (1-\gamma) \right\}} \quad (B30)$$

and:

$$\hat{I}_y^i = \frac{C_{fy}}{E_{fy}} = \frac{C_{fy} B_{P,fy}^{ex} q_P^i \psi_{fy}}{C_{P,fy}} \quad (B31)$$

Zone 1 (z1): <i>M. capensis</i> only	Zone 2 (z2): Mixed zone
<i>M. capensis</i> : biomass (B_C^{z1}), catch(C_C^{z1})	<i>M. capensis</i> : biomass (B_C^{z2}), catch(C_C^{z2}) <i>M. paradoxus</i> : biomass (B_P), catch(C_P)
Effort in zone 1 (E^{z1})	Effort in zone 2 (E^{z2})

Figure B.1: Diagrammatic representation of the two conceptual fishing zones.

Two species-aggregated CPUE indices are available: the ICSEAF West Coast and the ICSEAF South Coast series. For consistency, q 's for each species (and zone) are forced to be in the same proportion:

$$q_s^{SC} = r q_s^{WC} \quad (B32)$$

To correct for possible negative bias in estimates of variance (σ_y^i) and to avoid according unrealistically high precision (and so giving inappropriately high weight) to the CPUE data, lower bounds on the standard deviations of the residuals for the logarithm of the CPUE series have been enforced: for the historic ICSEAF CPUE series (separate West Coast and South Coast series) the lower bound is set to 0.25, and to 0.15 for the recent GLM-standardised CPUE series, i.e.: $\sigma^{ICSEAF} \geq 0.25$ and $\sigma^{GLM} \geq 0.15$.

The contribution of the CPUE data to the negative of the log-likelihood function (after removal of constants) is then given by:

$$-\lambda \ln L^{CPUE} = \sum_i \sum_y \left[\ln(\sigma_y^i) + (\varepsilon_y^i)^2 / 2(\sigma_y^i)^2 \right] \quad (B32)$$

where

σ_y^i is the standard deviation of the residuals for the logarithms of index i in year y .

Homoscedasticity of residuals for CPUE series is customarily assumed², so that $\sigma_y^i = \sigma^i$ is estimated in the fitting procedure by its maximum likelihood value:

$$\hat{\sigma}^i = \sqrt{1/n_i \sum_y (\ln(I_y^i) - \ln(\hat{I}_y^i))^2} \quad (B33)$$

where n_i is the number of data points for biomass index i .

In the case of the species-disaggregated CPUE series, the catchability coefficient q^i for biomass index i is estimated by its maximum likelihood value, which in the more general case of heteroscedastic residuals is given by:

$$\ln \hat{q}^i = \frac{\sum_y (\ln I_y^i - \ln \hat{B}_{fy}^{ex}) / (\sigma_y^i)^2}{\sum_y 1 / (\sigma_y^i)^2} \quad (B34)$$

In the case of the species-combined CPUE, $q_C^{WC,z1}$, $q_C^{WC,z2}$, q_P^{WC} , r and γ are estimated directly in the fitting procedure.

B.2.2 Survey biomass data

Data from the research surveys are available by region. For each region, they are treated as relative biomass indices in a similar manner to the species-disaggregated CPUE series above, with survey selectivity function S_a^{surv} replacing the commercial selectivity S_{fy} :

$$B_y^{r,surv} = \sum_{a=0}^m \tilde{w}_a^{surv} S_a^{surv} N_{ya}^r e^{-\nu^{surv}/12 M_a} \left(1 - \frac{\nu^{surv}}{12} \sum_f S_{fy} F_f^r \right) \quad (B35)$$

where ν^{surv} is the month in which the survey is taking place

An estimate of sampling variance is available for most surveys and the associated σ_y^i is generally taken to be given by the corresponding survey CV. However, these estimates likely fail to include all sources of variability, and unrealistically high precision (low variance and hence high weight) could hence be accorded to these indices. The procedure adopted takes into account a species-specific additional variance $(\sigma_A)^2$ which is

² There are insufficient data in any series to enable this to be tested with meaningful power.

treated as another estimable parameter in the minimisation process. This procedure is carried out enforcing the constraint that $(\sigma_A)^2 > 0$, i.e. the overall variance cannot be less than its externally input component.

The contribution of the survey data to the negative log-likelihood is of the same form as that of the CPUE biomass data (see equation B32). A single species-specific q per survey is estimated (i.e. same iq for all regions)

In June 2003, the trawl gear on the *Africana* was changed and a different value for the multiplicative bias factor q is taken to apply to the surveys conducted with the new gear. Calibration experiments have been conducted between the *Africana* with the old gear (hereafter referred to as the “old *Africana*”) and the *Nansen*, and between the *Africana* with the new gear (“new *Africana*”) and the *Nansen*, in order to provide a basis to relate the multiplicative biases of the *Africana* with the two types of gear (q_{old} and q_{new}). A GLM analysis assuming negative binomial distributions for the catches made (Brandão *et al.*, 2004) provided the following estimates:

$$\Delta \lambda nq^{capensis} = -0.494 \text{ with } \sigma_{\Delta \lambda nq^{capensis}} = 0.141 \quad \text{i.e. } (q^{new}/q^{old})^{capensis} = 0.610 \text{ and}$$

$$\Delta \lambda nq^{paradoxus} = -0.053 \text{ with } \sigma_{\Delta \lambda nq^{paradoxus}} = 0.117 \quad \text{i.e. } (q^{new}/q^{old})^{paradoxus} = 0.948$$

where

$$\lambda nq_{new}^s = \lambda nq_{old}^s + \Delta \lambda nq^s \quad \text{with } s = capensis \text{ or } paradoxus \quad (\text{B36})$$

No plausible explanation has yet been found for the particularly large extent to which catch efficiency for *M. capensis* is estimated to have decreased for the new research survey trawl net. It was therefore recommended (BENEFIT 2004) that the ratio of the catchability of the new to the previous *Africana* net be below 1, but not as low as the ratio estimated from the calibration experiments. $\Delta \lambda nq^{capensis}$ is therefore taken as -0.223, i.e. $(q^{new}/q^{old})^{capensis} = 0.8$.

The following contribution is therefore added as a penalty (or a log prior in a Bayesian context) to the negative log-likelihood in the assessment:

$$-\lambda n L^{q-ch} = (\lambda n q_{new} - \lambda n q_{old} - \Delta \lambda nq)^2 / 2\sigma_{\Delta \lambda nq}^2 \quad (\text{B37})$$

A different length-specific selectivity is estimated for the “old *Africana*” and the “new *Africana*”.

B2.3 Commercial proportions at length

Commercial proportions at length are not disaggregated by region. The model is therefore fit to the proportions at length as determined for a combination of regions, and in cases where the data are not disaggregated by species, a combination of species as well.

The catches at length are computed as:

$$C_{fyl} = \sum_r \sum_s \sum_{a=0}^m N_{sy}^r F_{sfy}^r S_{sfyl} P_{s,a+1/2,l} e^{-M_{sa}/2} \left(1 - \sum_f S_{sfya} F_{sfy}^r / 2 \right) \quad (\text{B38})$$

with the predicted proportions at length:

$$p_{yl}^i = C_{fyl} / \sum_l C_{fyl} \quad (\text{B39})$$

The contribution of the proportion at length data to the negative of the log-likelihood function when assuming an “adjusted” lognormal error distribution is given by:

$$-\lambda n L^{\text{length}} = 0.01 \sum_y \sum_l \left[\lambda n \left(\sigma_{len}^i / \sqrt{p_{yl}^i} \right) + p_{yl}^i \left(\lambda n p_{yl}^i - \lambda n \hat{p}_{yl}^i \right)^2 / 2(\sigma_{len}^i)^2 \right] \quad (\text{B40})$$

where

the superscript '*i*' refers to a particular series of proportions at length data which reflect a specified fleet, combination of regions, and species (or combination thereof); and

σ_{len}^i is the standard deviation associated with the proportion at length data, which is estimated in the fitting procedure by:

$$\hat{\sigma}_{len}^i = \sqrt{\sum_y \sum_l p_{yl}^i (\ln p_{yl}^i - \ln \hat{p}_{yl}^i)^2 / \sum_y \sum_l 1} \quad (B41)$$

The initial 0.01 multiplicative factor is a somewhat arbitrary downweighting to allow for correlation between proportions in adjacent length groups.

Commercial proportions at length are incorporated in the likelihood function using equation B40, for which the summation over length *l* is taken from length *l_{minus}* (considered as a minus group) to *l_{plus}* (a plus group). The length for the minus- and plus-groups are fleet specific and are chosen so that typically a few percent, but no more, of the fish sampled fall into these two groups.

B2.4 Commercial proportions at age

As for the proportions at length, commercial proportions at age are not disaggregated by regions. The model is therefore fit to the proportions at age as determined for a combination of region and in cases where the data are not disaggregated by species, a combination of species as well.

The catches at age are computed as:

$$C_{fya} = \sum_r \sum_s \sum_{l=1}^{l_{\max}} N_{sya}^r F_{sfy}^r S_{sfyl} P_{s,a+1/2,l} e^{-M_{sa}/2} \left(1 - \sum_f S_{sfya} F_{sfy}^r / 2 \right) \quad (B42)$$

with the predicted proportions at age:

$$\hat{p}_{ya}^i = C_{fya} / \sum_{a'} C_{fya'} \quad (B43)$$

The contribution of the proportion at age data is as for the proportions at length (equation B40), except that the multiplicative downweighting factor is fixed at 0.1 instead of 0.01.

B.2.5 Survey proportions at length

Survey proportions at length are available by region. They are incorporated into the negative of the log-likelihood in an analogous manner to the commercial catches-at-length, assuming an adjusted log-normal error distribution (equation B40). In this case however, data are disaggregated by species, and by region:

$p_{syl}^{r,surv} = \frac{C_{syl}^{r,surv}}{\sum_{l'} C_{syl'}^{r,surv}}$ is the observed proportion of fish of species *s*, and length *l* from survey *surv* in year *y* in region *r*; and

$\hat{p}_{syl}^{r,surv}$ is the expected proportion of fish of species *s*, and length *l* in year *y* and region *r* in the survey *surv*, given by:

$$\hat{p}_{syl}^{r,surv} = \frac{\sum_a S_{sl}^{surv} P_{s,a+1/2,l} N_{sya}^r e^{\frac{-\nu^{surv}}{12} M_{sa}} \left(1 - \frac{\nu^{surv}}{12} \sum_f S_{sfya} F_{sfy}^r \right)}{\sum_{l'} \sum_a S_{sl'}^{surv} P_{s,a+1/2,l'} N_{sya}^r e^{\frac{-\nu^{surv}}{12} M_{sa}} \left(1 - \frac{\nu^{surv}}{12} \sum_f S_{sfya} F_{sfy}^r \right)} \quad (B44)$$

B.2.6 Stock-recruitment function residuals

The stock-recruitment residuals are assumed to be log-normally distributed. Thus, the contribution of the recruitment residuals to the negative of the log-likelihood function is given by:

$$-\lambda n L^{SR} = \sum_s \left[\sum_{y=y1}^{y2} \zeta_{sy}^2 / 2\sigma_R^2 \right] \quad (\text{B45})$$

where

ζ_{sy} is the recruitment residual for species s , and year y , which is assumed to be log-normally distributed with standard deviation σ_R and which is estimated for year $y1$ to $y2$ (estimating the stock-recruitment residuals is made possible by the availability of catch-at-length data, which give some indication of the age-structure of the population); and

σ_R is the standard deviation of the log-residuals, which is input.

The stock-recruitment residuals are estimated for years 1985 to 2006, with recruitment for other years being set deterministically (i.e. exactly as given by the estimated stock-recruitment curve) as there is insufficient catch-at-age information to allow reliable residual estimation for earlier years. A limit on the recent recruitment fluctuations is set by having the σ_R (which measures the extent of variability in recruitment) decreasing linearly from 0.45 in 2004 to 0.1 in 2013, effectively forcing recruitment over the last years to lie closer to the stock-recruitment relationship curve.

B.3 Model parameters

B.3.1 Estimable parameters

The primary parameters estimated are the species-specific female virgin spawning biomass ($K_s^{\varphi_{sp}}$) and “steepness” of the stock-recruitment relationship (h_s). The standard deviations σ^i for the CPUE series residuals (the species-combined as well as the GLM-standardised series) as well as the additional variance (σ_A^i)² for each species are treated as estimable parameters in the minimisation process. Similarly, in the case of the species-combined CPUE, $q_C^{WC,z1}$, $q_C^{WC,z2}$, q_P^{WC} , r and γ are directly estimated in the fitting procedure.

The value of β used to compute the standard deviation of the length-at-age a is also estimated in the fitting procedure.

Table B.1 summarises the estimable parameters, excluding the selectivity parameters.

The following parameters are also estimated in the model fits undertaken (if not specifically indicated as fixed).

B.3.1.1 Stock-recruitment residuals

Stock-recruitment residuals ζ_{sy} are estimable parameters in the model fitting process. They are estimated separately for each species from 1985 to the present, and set to zero pre-1985 because there are no catch-at-length data for that period to provide the information necessary to inform estimation.

B.3.1.2 Survey fishing selectivity-at-length

The survey selectivities are estimated directly for seven pre-determined lengths for *M. paradoxus* and *M. capensis*. When the model was fit to proportion-at-age rather than proportion-at-length data, survey selectivities were estimated directly for each age (i.e. seven age classes). The lengths at which selectivity is estimated directly are given in Table B.2. Between these lengths, selectivity is assumed to change linearly. The

slope from lengths l_{minus} to $l_{minus}+1$ is assumed to continue exponentially to lower lengths down to length 1, and similarly the slope from lengths $l_{plus}-1$ to l_{plus} for *M. paradoxus* and *M. capensis* to continue for greater lengths.

A penalty is added to the total $-lnL$ to smooth the selectivities to smooth the selectivities by penalising deviations from straight line dependence (the choice of a weighting of 3 was made empirically to balance this term having sufficient but not undue influence) :

$$pen^{survS} = \sum_i \sum_{L=L_1+1}^{L_7-1} 3(S_{L-1}^s - 2S_L^s + S_{L+1}^s)^2 \quad (B46)$$

B.3.1.3 Commercial fishing selectivity-at-length

The fishing selectivity-at-length (gender independent) for each species and fleet, S_{sf} , is estimated in terms of a logistic curve given by:

$$S_{sf} = [1 + \exp(-\left(l - l_{sf}^c\right)/\delta_{sf}^c)]^{-1} \quad (B47)$$

where

l_{sf}^c cm is the length-at-50% selectivity,

δ_{sf}^c cm⁻¹ defines the steepness of the ascending limb of the selectivity curve.

Periods of fixed and changing selectivity have been assumed for the offshore trawl fleet to take account of the change in the selectivity at low ages over time in the commercial catches, likely due to the phasing out of the (illegal) use of net liners to enhance catch rates.

B.3.2 Input parameters and other choices for application to hake

B.3.2.1 Length-at-maturity

The proportion of fish of species s and length l that are mature is assumed to follow a logistic curve with the parameter values given below (from Singh et al. 2011)):

Table B.1: Female maturity-at-length logistic curve parameter values for the new Reference Case.

	l_{50} (cm)	Δ
<i>M. paradoxus</i>	41.53	2.98
<i>M. capensis</i>	53.83	10.14

B.3.2.2 Weight-at-length

The weight-at-length for each species and gender is calculated from the mass-at-length function, with values of the parameters for this function listed below (from Fairweather 2008, taking the average of the West and South coasts):

Table B.2: Weight-at-length parameter values.

	α (gm/cm ³)	β
<i>M. paradoxus:</i>	0.00669	3.02675
<i>M. capensis:</i>	0.00605	3.07313

B.3.2.3 Minus- and plus-groups

Because of a combination of gear selectivity and mortality, a relatively small number of fish in the smallest and largest length classes are caught. In consequence, there can be relatively larger errors (in terms of variance) associated with these data. To reduce this effect, the assessment is conducted with minus- and plus-groups obtained by summing the data over the lengths below and above l_{minus} and l_{plus} respectively. The minus- and plus-group used are given in Table B4. Furthermore, the proportions at length data (both commercial and survey) are summed into 2cm length classes for the model fitting.

Table B.1: Parameters estimated in the model fitting procedure, excluding selectivity parameters.

	No of parameters	Parameters estimated	Bounds enforced
K	2	$\ln(K_{cap}^2)$ and $\ln(K_{para}^2)$	(3.5; 9.0)
Stock-recruitment h	2	h_{cap} and h_{para}	(0.2; 0.98)
Stock-recruitment γ	2	γ_{cap} and γ_{para}	(0;10)
Additional variance	2	$\sigma_{A,cap}$ and $\sigma_{A,para}$	(0; 0.5)
Recruitment residuals	56	$\zeta_{cap,1985-2013}$ and $\zeta_{para,1985-2013}$	(-5; 5)
σ_{CPUE}	6	1 for each series	ICSEAF: (0.25; 1), GLM (0.15; 1)
ICSEAF CPUE	5	$q_c^{WC,z1}, q_c^{WC,z2}, q_p^{WC}, \rho$ and γ	q and ρ : (0,10), and γ_R (0; 1)
Age-length distribution	2	For each species: β_i	(0.4;1.0)
Survey calibration	4	$\Delta \ln q^{SPP}$ and $\sigma_{\Delta \ln q^{SPP}}$ for each species	(-1;1) and (0;0.5)
Selectivities	34	see Table B3	
Movement parameters	234	see Table 2
